Problem Set 1: Understanding Type I Error Rates

27 September, 2022

You start a new rotation in a lab that studies the effect of different compounds on the ability of mice to form new memories. You learn that the lab has been following a protocol that involves testing each compound on 10 mice, and using another 10 mice treated with a placebo as a control. If the first analysis doesn't yield a p-value passing the statistical significance threshold of 0.05, the standard practice in the lab is to add another 10 mice to each group and perform a second analysis with 20 animals per group.

Part I

Show, using a simulation in R, that when a compound really has no effect, the Type I error rate of the first analysis is 5%.

Part II

Using a simulation in R, show that the Type I error rate for the overall protocol that the lab is using is increased by approximately 70%.

What percentage of the time will this lab conclude that ineffective compounds have an effect?

Part III

What alpha value should the lab be using to maintain an overall Type I error rate of 5% when following their protocol?
